Resumo

Elemento obrigatório, constituído de uma sequência de frases concisas e objetivas, em forma de texto. Deve apresentar os objetivos, métodos empregados, resultados e conclusões. O resumo deve ser redigido em parágrafo único, conter no máximo 500 palavras e ser seguido dos termos representativos do conteúdo do trabalho (palavras-chave).

Palavras-chave: palavra-chave1, palavra-chave2, palavra-chave3.

Abstract

Elemento obrigatório, elaborado com as mesmas características do resumo em língua portuguesa.

Keywords: keyword1, keyword2, keyword3.

Chapter 1

Concepts

1.1 Statecharts and Automata

A software specification is a reference document which contains the requisites the program should satisfy. It can also be understood as a model of how the system should behave. A specification may be developed with natural language, with user cases for example, or using formal software engineering techniques.

Statecharts are a type of formal software specification based on finite states machines (FSM) specially used in complex systems modeling, such as reactive systems and were defined in [3]. Similar to an automaton, a statechart has sets of states, transitions and input events that cause change of state. However, a statechart has additional features: orthogonality, hierarchy, broadcasting and history.

1.1.1 Nondeterministic finite automata

Definition[4]: A nondeterministic finite automaton is a quintuple $M = (K, \Sigma, \Delta, s, F)$, where:

- K is the set of states
- Σ is the input alphabet
- Δ is the transition relation, a subset of $K \times (\Sigma \cup e) \times K$, where e is the empty string
- $s \in K$ is the initial state
- $F \subseteq K$ is the set of final states

Each tripe $(q, a, p) \in \Delta$ is a transition of M . If M is currently in state q and the next input is a , then M may follow any transition of the form (q, a, p) or (q, e, p) . In the later case, no input is read. A configuration of M is an element of K^* and the relation \vdash (yields one step) between two configurations is defined as: $(q, w) \vdash (q', w') \Leftrightarrow$ there is a $u \in \Sigma \cup e$ such that $w = uw'$ and $(q, u, q') \in \Delta$.

Further information and formalism regarding finite automata can be obtained in [4].

A nondeterministic finite automaton example

Find below an example of a nondeterministic finite automaton extracted from [4].

- $K = \{q_0, q_1, q_2\}$

- $\Sigma = \{a, b\}$
- $\Delta = \{(q_0, a, q_1), (q_1, b, q_2), (q_2, a, q_0), (q_2, e, q_0)\}$
- $s = q_0$
- $F = \{q_0\}$ is the set of final states

Figure 1.1: A nondeterministic finite automaton that accepts language $L = (ab \cup aba)^*$.

1.1.2 Statechart models

A statechart model can be considered an extended finite state machine. The syntax of statechart is defined over the set of states, transitions, events, actions, conditions, expressions and labels [3]. In short terms:

- Transitions are the relations between states
- Events are the input that might cause a transition to happen
- Actions are generally triggered when a transition occurs
- Conditions are boolean verifications added to a transition in order to restrict the occurrence of that transitions
- Expressions are composed of variables and algebraic operations over them
- A label is a pair made of an event and an action that is used to label a transition

Furthermore, it is worth noting that a statechart model possesses other features, described over the next sections of this chapter, that do not appear in a common finite state machine. These extra resources are useful, for instance, to model concurrency and different abstraction levels in a more practical way.

Orthogonality

More than one state may be active at the same time in a statechart, which is called orthogonality. It can be used to model concurrent and parallel situations. The set of active states in a certain moment is called configuration. In figure 1.2, parallel regions inside the state *Clock*: *r1* and *r2*. At the same moment, then, states *Display* and *AlarmOff* can be active.

Figure 1.2: Statechart example. A clock model.(@@@@ CITAR REFERENCIA DO YAKINDU)

Hierarchy

It is possible that a state contains other states, called substates, and internal transitions, increasing the abstraction and encapsulation level of the model. In figure 1.2, we have that *Display*, *Settings*, *AlarmOff*, *AlarmOn* and *AlarmRinging* are sub-states of *Clock*. *Display* also contains the sub-states: *DisplayHour*, *DisplayMinutes* and *hist*. And the states *SetHour*, *SetMinutes* and *ActivateAlarm* are inside state *Settings*.

Guard conditions

In a transition, a guard condition is always verified before the change of states take place. If the condition is satisfied, in other words, the expression returns true, the transition will happen. Otherwise, that transition is not allowed to happen. An expression in a guard condition involves variables and operations. It is possible to check whether a state was entered for example. In figure 1.2, the transition from *AlarmOff* to *AlarmOn* is guarded by the condition *[alarm]*, meaning that the transition will only happen if the value of the variable *alarm* is true.

Broadcasting

Besides an input event, a transition might have an action that is triggered when the transition is done. An action may cause another transition to happen, that is called broadcasting. This feature makes it possible that chain reactions occur in a statechart model. Consider figure 1.2, if we are currently in states *ActivateAlarm* and *AlarmOff* and the *mode* event occurs, we will have the following situation: the transition will be executed and we will stay at state *ActivateAlarm*, the value of variable *alarm* will be changed to its opposite (let's suppose it was *false*, so now it will be *true*) and we will also go to state *AlarmOn* since the condition *[alarm]* guarding the transition between these last two states is satisfied. There-

fore, not only the transition starting at *ActivateAlarm* happened when *mode* occurred, but also the transition between *AlarmOff* and *AlarmOn*. The change of the value of variable *alarm* was broadcasted to the whole statechart and a chain reaction happened.

History

A statechart is capable of remembering previously visited states by accessing the history state. Considering figure 1.2, suppose we are in state *DisplayMinutes* and event *set* happened three times in a row. So, we went to *SetHour*, and then *SetMinutes* and now we are at *ActivateAlarm*. If there is another occurrence of *set* we will be directed to the history state *hist*. Since the last active sub-state in *Display* was *DisplayMinutes*, we will actually be directed to *DisplayMinutes*.

A statechart and its corresponding automaton

It is possible to get an automaton from a statechart by flattening the statechart. The hierarchy and cocurrency need to be eliminated. In addition, statechart elements such as guard conditions and actions are not present in an automaton.

The following examples were extracted from [3]. In figure 1.3 we have a statechart and in figure 1.4 we have the flat version that would correspond to an automaton.

Figure 1.3: A statechart model with hierarchy and concurrent regions

To flat a statechart and get the corresponding automaton, we need to pass transitions from the composed states to their sub-states to eliminate the hierarchy. To remove orthogonality, we need to do the product of the states in each concurrent region. Such operation causes will cause state and transition explosions in the automaton if the original statechart model has many concurrent states. Besides, in the statechart we can make usage of guard transitions and broadcasting, enriching the model with more information. Note that in the

Figure 1.4: *The statechart from 1.3 after flattening to the corresponding automaton*

automaton, the initial state is the product of the initial states from each parallel region in the statechart.

1.2 Tests

Since code has been written, programs have been tested. Testing is one of the most important means of assessing the software quality and it typically consumes from 40% up to 50% of the software development effort [5]. Therefore, it constitute an important area in software engineering.

Testing evolved from an activity related debugging code to way of checking specification, design as well as implementation[5]. It can be considered a process not only to detect bugs, but to also prevent them [2].

1.2.1 Testing goals

In a organization, the goals of testing vary depending on the level of maturity of the team [1]: At a more inexperienced approach, testing could be viewed as the same as debugging the code. A further step would be to consider testing as the process to make sure that a software does what it is supposed to do. But, in this case, if a team runs a test suite and every test case passed, should the team consider that the software is correct or could it be that the test cases were not enough? How does the team decide when to stop?

A different perspective, then, would be to understand testing as the process of finding errors. Therefore a successful test case would be the one that indicated an error in the system [8]. Although discovering unexpected results and behaviour is a valid goal, it might put tester and developers in an adversarial relationship, which certainly damages the team interaction.

Testing shows the presence, but not the absence of errors. Hence, realizing that when executing a software we are under some risk that may have unimportant or great consequences leads to another way to see the intention of the test process: to reduce the risk of using the program, an effort that should be performed by both testers and developers.

Thus, testing can be seen as a mental discipline that helps all professionals in the software industry to increase quality. [1]. The whole software development process could benefit

from that thinking: Design and specification would be more clear and precise and the implementation would have fewer errors and would be more easily validated, for example.

1.2.2 The process of testing

Since testing is a time consuming activity, the creation of test cases can be done during each stage of the development process, even though their execution will only be possible after some part of the code is implemented.

V-Model

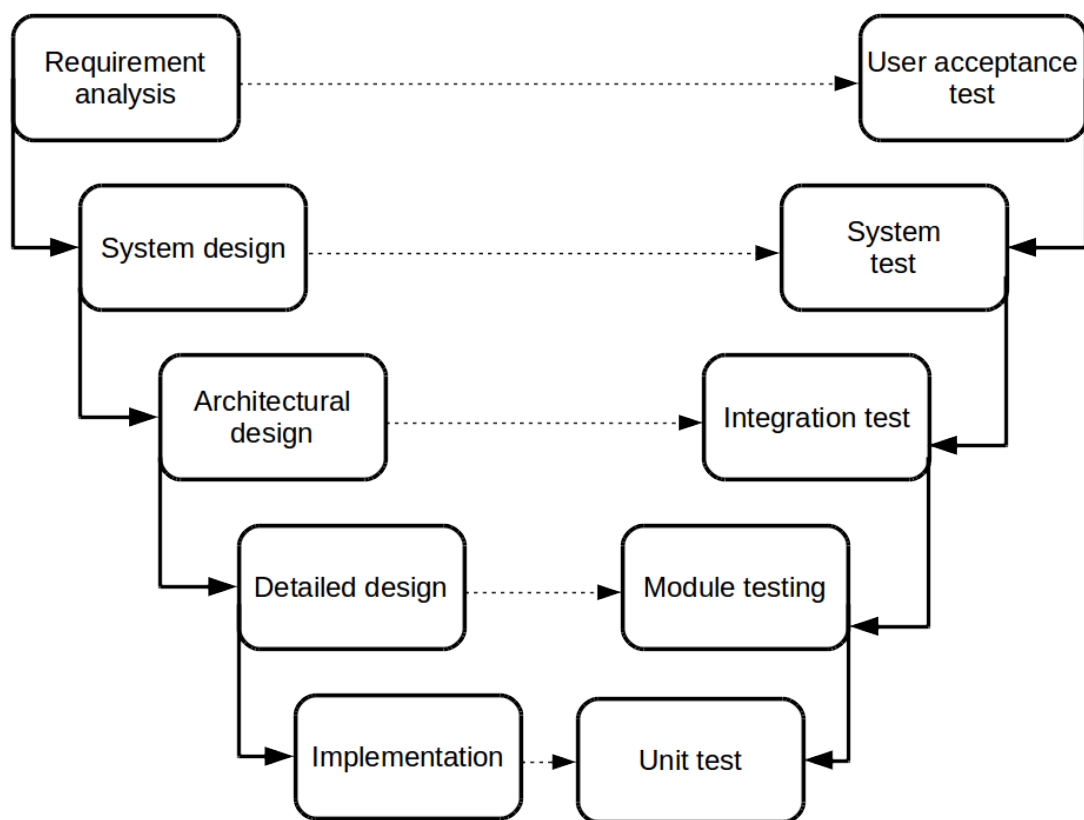

Figure 1.5: *The V-model*

The V-model in figure 1.5 associates each level of testing to a different phase in the development process. This model is typically viewed as an extension of the waterfall methodology, but it does not mandatorily implies the waterfall approach since the synthesis and anlysis activities generically apply to any development process [1].

- requirement analysis phase: Customer's needs are registered. **User acceptance tests (UAT)** are constructed to validated that the delivered system meets the customer's requirements.
- System design phase: Technical team analyzed the captured requirements and study the possibilities to implement them and document a technical specification. **System**

tests are designed at this stage assuming that all pieces work individually and checks if the system works as a whole.

- Architectural design phase: Specify interface relationships, dependencies, structure and behaviour of subsystems. **Integration tests** are developed, with the assumption that each module works correctly, in order to verify all interfaces and communication among subsystems.
- Detailed design phase: A low-level design is done to divide the system in smaller pieces, each one of them with the corresponding behaviour specified so that the programmer can code. **Module testing** is designed to check each module individually.
- Implementation phase: Code is actually produced. **Unit tests** are designed to test every smallest unit of code, such a method, can work correctly when isolated.

1.2.3 Functional and Structural tests

Testing techniques can be divided in functional and structural categories.

Functional technique (black box)

Functionalities described in the specification are considered to create the test cases. It is necessary to study the behaviour and functionalities presented, develop the corresponding test cases, submit the system to the test cases and analyze the results observed comparing them to what was expected according to the description in the specification. Examples of criteria in this technique[6]:

- **Equivalence classes partitioning**

Input data are partitioned into valid and invalid classes according to the conditions specified. The test cases are created based on each class by selecting a element in each class are a representative of the whole class. Using this criterion, the test cases can be executed systematically according to the requisites.

- **Analysis of the boundary value**

Similar to the previous criterion, but the selection of the representative is done based on the classes' boundary. For that reason, the conditions associated with the limit values are exercised more strictly.

Since many specifications are written in descriptive way, the test cases developed using the functional technique can be informal and not specific enough, which makes it difficult to automate their execution and human intervention becomes necessary. However, this technique only requires that requisites, input and corresponding output are identified. Thus, it can be applied during several testing phases, such as integration and system.

Structural technique (white box)

The structure of the code implementation is considered to create the test cases. In this technique, the program is represented by an oriented graph of flow control, in which each vertex corresponds to a block of code, a statement in the code for instance, and each edge corresponds to a transition between the blocks. The criteria related to this technique are generally concerned with the coverage of the program graph, such as [1]:

- **Node coverage**

Every reachable node in the graph must be exercised by the test set. Node coverage is implemented by many testing tools, most often in the form of statement coverage

- **Edge coverage**

Every edge in the graph must be tested in the test set.

- **Complete path coverage**

All paths in the graph must be tested by the test set. This criterion is infeasible if there are cycles in the graph due to the infinity number of paths.

- **Prime path coverage**

A path is a prime path if it is a simple path and it does not appear as a proper subpath of any other simple path. In this criterion, all prime paths should be tested.

- **Specified Path Coverage**

A specific set S of paths is given and the test set must exercise all paths in S . In situation might occur if the use scenarios provided by the customer are converted to paths in the graph and the team wishes to test them.

Tests obtained via structural technique contribute specially to code maintenance and increase the reliability of the implementation. But, they do not represent a way to validate the system against customer's requirements, since the specified requisites are not considered in their design.

Chapter 2

Test cases

In this section, we will be concerned with test case creation from the functional perspective. The structure of the code will not be analyzed. Instead, the specifications with the requisites are going to be the source to derive the test cases.

2.1 Designing test cases

For simple programs, a test case might be a pair composed by the software input and the expected output. But, for more complex software, such as web applications or reactive systems, a test case can be a series of consecutive steps or events and their expected consequence.

Given a specification, a test engineer can systematically design test cases: for each functionality defined, use the equivalence class partitioning technique described in 1.2.3 to select the input representatives; enumerate the steps necessary to activate the functionality; and add the expected outputs.

One test case example to test the login of an online store would be the following:

@@@@@ ADICIONAR EXEMPLO DE CASO DE TESTE DE LOGIN

It is also interesting to project test cases for negative scenarios, in which the program should handle an incorrect action done by the user. A test engineer could consider the following:

@@@@@ ADICIONAR EXEMPLO DE CASO DE TESTE DE LOGIN - CENARIO NEGATIVO

2.1.1 Use cases vs Test cases

More detailed use cases provide a series of steps to perform flows related to a determined functionality. Each step might contain the description of system behaviour and user actions. There are also preconditions so that the use case be considered for execution and an actor is associated with the case. Besides, one use case might describe more than one flow for the functionality by extending the basic flow.

@@@@@ ADICIONAR EXEMPLO DE CASO DE USO DE LOGIN

In a test case, however, one step has to specify one single action and its corresponding consequence in the system. We can add preconditions to each step in a test case, even if the precondition is that the previous step was executed successfully. In addition, it is not possible to have more than one flow in one test case, otherwise the tester would have no clear direction during the test run. Therefore, we need to create test cases for each flow.

An use case serves as an guide for during the implementation process used by developers. It is a way to understand how the functionality is being coded is going to be used. An use case will not be executed directly. Test cases are used to direct tester regarding the precise actions that should be performed in each flow and are a way to detect errors. They are directly executed during the test phase.

Use cases are a great source for the creation of test cases because they detail main flows and contain action steps. However, they are different in structure and purpose; therefore, one cannot replace the other.

2.2 Automatic generation of test cases

A model, a statechart for instance, can also be used to specify certain scenarios and functionalities relevant to the software. Considering that such model is correct, one can use it to automatically generate functional test cases [7]. This technique, in which test cases are automatically derived from a model, is called Model Based Test.

2.3 Test cases for statecharts

2.3.1 Test case for simple statecharts

2.3.2 Test case for complex statecharts: hierarchy

2.3.3 Test case for complex statecharts: orthogonality
